Homework 4

Ankur Patel
October 13, 2020

Note: Because some problems were taking very long to run, I could not get the output. I generated the pdf by commenting out the parts that were running for a long time. I then uncommented them when I pushed the markdown to git.

Problem 2: Using the dual nature to our advantage

```
set.seed(1256)
#generate the data
theta \leftarrow as.matrix(c(1,2),nrow=2)
X \leftarrow cbind(1,rep(1:10,10))
h <- X%*%theta+rnorm(100,0,0.2)
#fit the linear model using lm, print the coefficients
lm_fit \leftarrow lm(h \sim 0 + X)
print(lm_fit)
##
## Call:
## lm(formula = h \sim 0 + X)
##
## Coefficients:
##
       X1
                X2
## 0.9696 2.0016
#tol is the tolerance
tol <- 1e-6
#alpha is the step size
alpha \leftarrow 1e-2
theta_curr \leftarrow as.matrix(c(0.5,1),nrow =2)
grad_descent <- function(theta_curr,alpha,m,X,h,tol,max_iter)</pre>
  iter <- 1
  theta_new <- theta_curr - (alpha/m)*t(X)%*%(X%*%theta_curr-h)
  while((abs(theta_curr[1]-theta_new[1])) > tol && (abs(theta_curr[2]-theta_new[2])) > tol)
    if (((abs(theta_curr[1]-theta_new[1])) < tol && (abs(theta_curr[2]-theta_new[2]) < tol)) || (iter >
      theta_final <- theta_new</pre>
      return(c(theta_final,max_iter))
    theta_curr <- theta_new</pre>
    theta_new <- theta_curr - (alpha/m)*t(X)%*%(X%*%theta_curr-h)
```

```
}
print(grad_descent(theta_curr,alpha,m,X,h,tol,max_iter = 1000))
```

```
## [1] 0.9305694 2.0071652 1000.0000000
```

The tolerance I used was 1e-6 and $\alpha = 1e - 2$. For lm,the estimate for θ_0 was 0.9696 and for theta₁ it was 2.0016. I capped the number of iterations at 1000 and the final values were 0.8707 for θ_0 and 2.0158 for θ_1 for gradient descent; compared to lm, gradient descent did slightly worse.

Problem 3: Gradient Descent

```
set.seed(12456)
library(foreach)
library(parallel)
#make the cluster, set the number of cores
# cores <- max(1,detectCores()-1)</pre>
# cl <- makeCluster(cores)</pre>
#maximum number of iterations
max_iter <- 5000
runs <- 100
#sample from a uniform (-1,1) which will helps us get theta_start
U <- runif(runs,-1,1)</pre>
#the vector of starting values
theta0 start <- 1 + U
theta1_start <- 2 + U
theta_start <- cbind(theta0_start,theta1_start)</pre>
#step size and tolerance
alpha <- 1e-7
tol <- 1e-9
#run gradient descent in parallel
# foreach (i=1:runs,.combine="rbind") %do%
# {
    grad_descent(theta_start[i,],alpha,m,X,h,tol,max_iter = max_iter)
# stopCluster(cl)
```

If we changed the stopping rule to include our knowledge of the true value, it could improve accuracy by ensuring that we converge to the right solution because the tolerance would be with respect to the solution and the true value. On the other hand, it could cause the gradient descent algorithm to run for a very long time to achieve convergence. This algorithm works well if we choose α and the tolerance reasonably well. However, if we don't it can run endlessly.

Even in parallel, this computation was taking my computer over 3 hours to run; I was not able to get any results.

Problem 4: Inverting Matrices

We would need to compute X'X and then factorize it to make the inversion less expensive. Since X'X is symmetric, we could find a suitable decomposition for symmetric matrices. In the current computation, we are computing and then inverting X'X which is expensive and then multiplying by X'y.

Problem 5: Need for speed challenge

```
set.seed(12456)
G <- matrix(sample(c(0,0.5,1),size=16000,replace=T),ncol=10)</pre>
R \leftarrow cor(G) \# R: 10 * 10 correlation matrix of G
C <- kronecker(R, diag(1600)) # C is a 16000 * 16000 block diagonal matrix
id <- sample(1:16000, size=932, replace=F)</pre>
q <- sample(c(0,0.5,1),size=15068,replace=T) # vector of length 15068</pre>
A <- C[id, -id] # matrix of dimension 932 * 15068
B <- C[-id, -id] # matrix of dimension 15068 * 15068
p \leftarrow runif(932,0,1)
r <- runif(15068,0,1)
#print the sizes of A and B
print(object.size(A))
## 112347208 bytes
print(object.size(B))
## 1816357192 bytes
# system.time(y <- p + A %*\% solve(B)%*\%(q-r))
C<-NULL #save some memory space
# chol B <- chol(B)
# system.time(y \leftarrow p + A %*% chol2inv(chol_B)%*%(q-r))
```

A is 112347208 bytes, B is 1816357192 bytes. Without any optimization tricks, it took about 12.4 minutes to calculate y. It makes the most sense to try to decompose B and then take the inverse to speed up the calculation. I tried using the cholesky decomposition and then chol2inv but it is still not able to compute it fast.

Problem 3 Proportion of Successes:

```
y <- rbinom(10,1,p)
return(y)
}
test_gen_flips <- gen_flips(0.25)
print(test_gen_flips)

## [1] 0 0 0 0 0 0 0 0 0 1

prob_vector <- seq(31,40)/100
P4b_data_corrected <- sapply(X = prob_vector,FUN = gen_flips)
row_prop_correct <- apply(P4b_data_corrected,1,calc_prop_success)
col_prop_correct <- apply(P4b_data_corrected,2,calc_prop_success)
print(row_prop_correct)

## [1] 0.8 0.3 0.5 0.5 0.4 0.2 0.9 0.4 0.1 0.1

print(col_prop_correct)</pre>
```

For the proportion of success by row, we get 0's and 1's whereas for the proportion of success by column, we get 0.6 every time. It is using the first probability, 31/100 each time and since the seed is fixed, we get the same outcome.

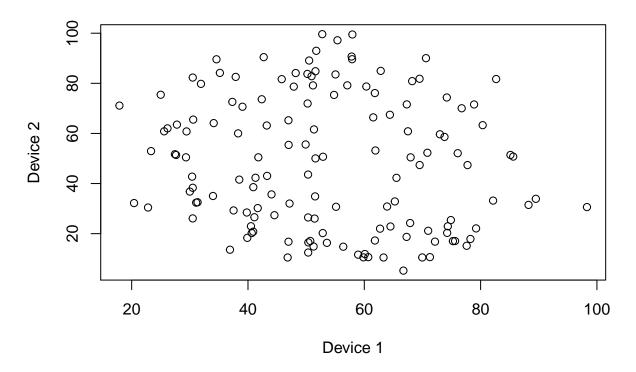

Problem 4 Observers Data:

[1] 0.3 0.4 0.3 0.4 0.6 0.3 0.3 0.5 0.6 0.5

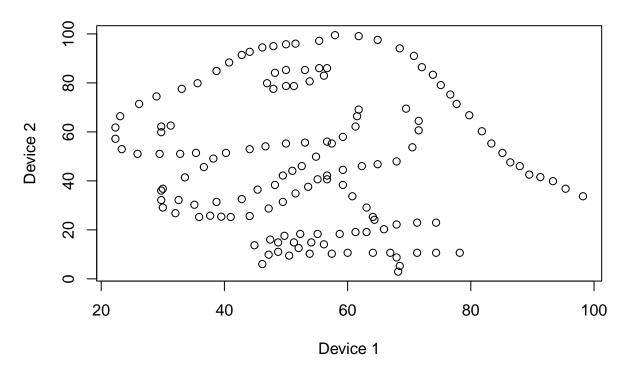

```
#read the data, rename columns and extract the Observers
devices_dat <- readRDS("D:/Downloads/HW3_data.rds")
names(devices_dat) <- c("Observer","x","y")
Observer_cat <- unique(devices_dat$Observer)

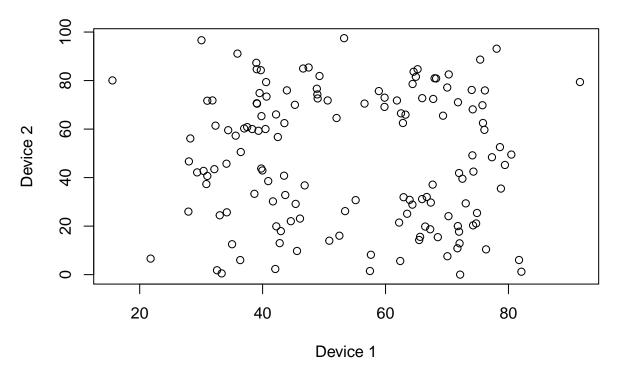

#create my plotting function
my_plotfun <- function(Y = devices_dat,index,title = "Devices by Observer",xlab = "Device 1",ylab = "De
```

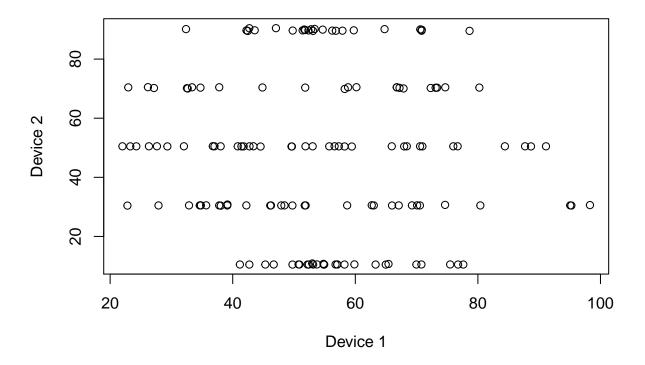

Entire Dataset

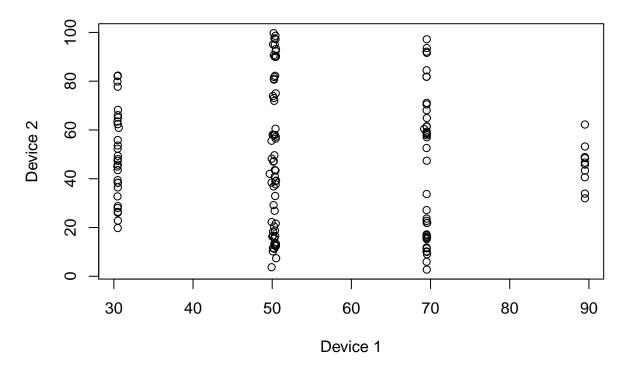

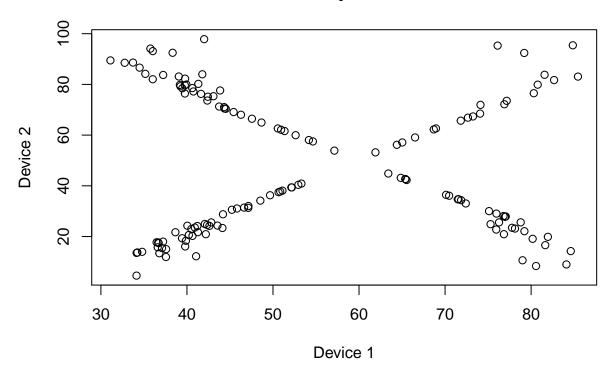

```
#plot the different Observers
multiplot <- sapply(X = Observer_cat,FUN = my_plotfun,Y=devices_dat,xlab="Device 1", ylab = "Device 2",</pre>
```

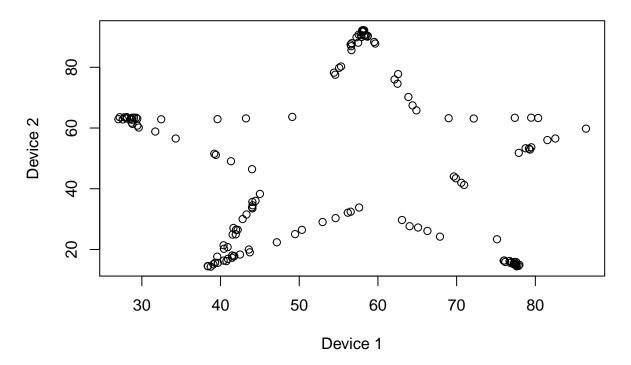

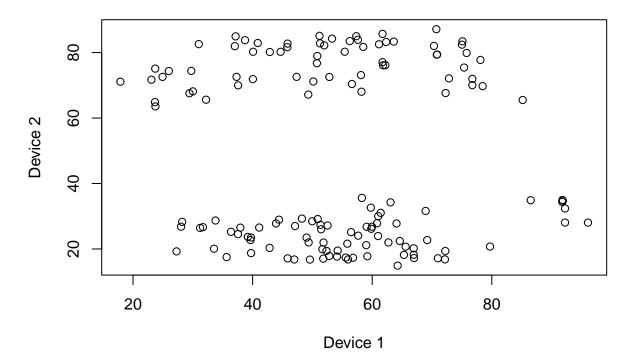

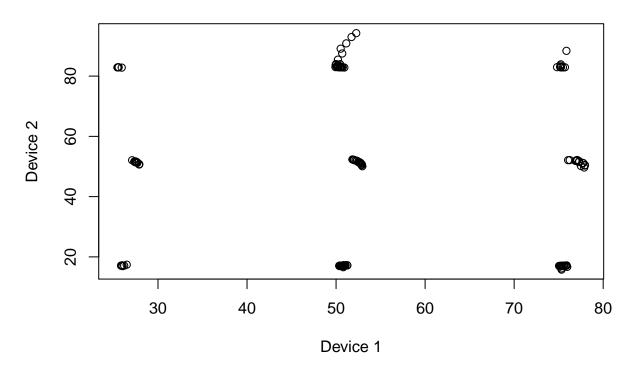

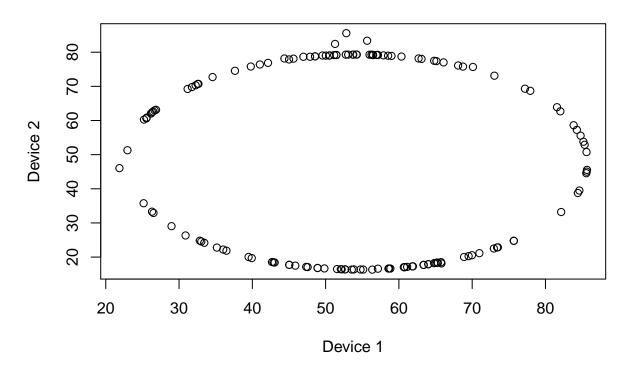

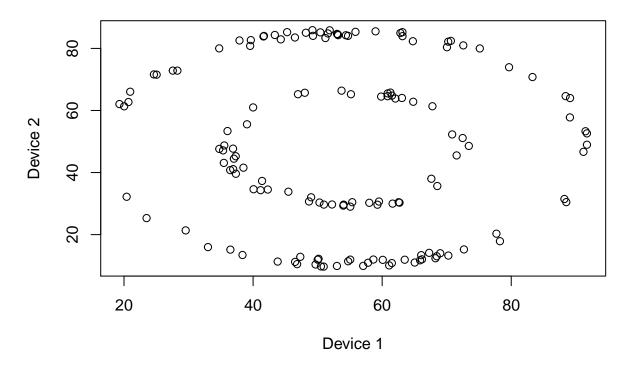

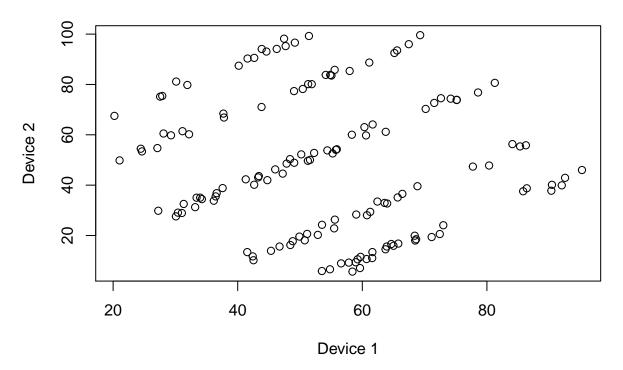

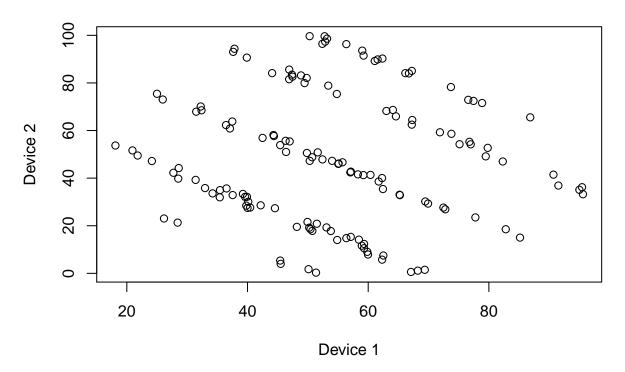

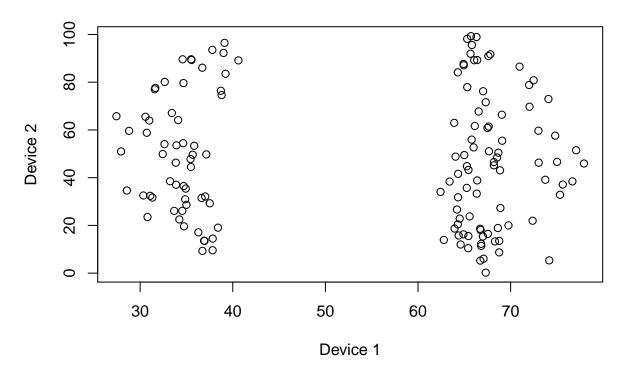

multiplot

```

Problem 5: Map

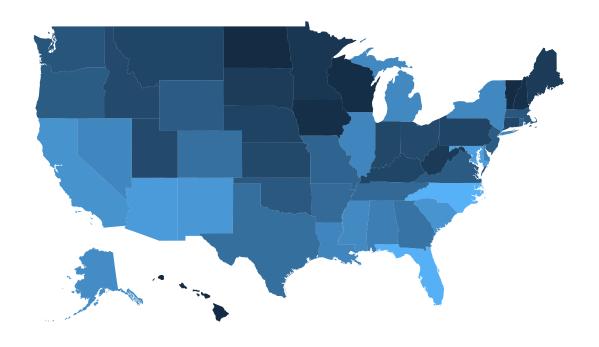

```
#I unzipped the file directly and put the data directly into my project #file. Then I just read in the
library(data.table)
states \leftarrow fread("states.sql", skip = 23, sep = "'", sep2 = ",", header = F, select = c(2,4))
cities_ext <- fread("cities.sql",skip = 23,sep = "'", sep2 = ",", header = F, select = c(2,4))
#take out DC from states and make a new dataframe
states_noDC <- states[-8,]</pre>
#build a dataframe for number of cities by state
num_cities_bystate <- vector()</pre>
for (i in 1:50)
{
  curr_state <- states_noDC[i,2]</pre>
  curr_state_long <- states_noDC[i,1]</pre>
  curr_cities <- subset(cities_ext, V4 == toString(unlist(curr_state)))</pre>
  curr_num_cities <- dim(curr_cities)[1]</pre>
  curr_row <- c(tolower(toString(unlist(curr_state_long))),toString(unlist(curr_state)),curr_num_cities</pre>
  num_cities_bystate <- rbind(num_cities_bystate,curr_row)</pre>
num_cities_bystate <- data.frame(num_cities_bystate)</pre>
## Warning in data.row.names(row.names, rowsi, i): some row.names duplicated:
## 2,3,4,5,6,7,8,9,10,11,12,13,14,15,16,17,18,19,20,21,22,23,24,25,26,27,28,29,30,31,32,33,34,35,36,37,
## --> row.names NOT used
#name the columns
colnames(num_cities_bystate) <- c("State", "State_Short", "Num_Cities")</pre>
num_cities_bystate$Num_Cities <- as.numeric(num_cities_bystate$Num_Cities)</pre>
#make a table
knitr::kable(num_cities_bystate)

```

The supplied code in stack exchange failed to generate different samples on each run; for some reason it remained stuck at the same sample thus giving the same results. It is possible to do the bootstraps in parallel because the bootstrap sampling is done independently of other samples. Based on the difference in elapsed time, the small number of bootstrap samples, and the small data size I would say that it makes little difference computing in series vs parallel for this problem. The mean of the estimated β_0 was 2.4194 and the mean of the estimated β_1 was 0.2046.

0.1

Parallel

Problem 3: Newtons Method

```
#the grid we will search over
grid <- seq(-20,0,length.out = 100)
#orig_function is the original function
orig_function <- function(x)
{
    orig <- 3^x-sin(x)+cos(5*x)
    return(orig)
}
#plot the original function from -20 to 0
curve(orig_function,from = -20,to = 0)</pre>
```

```
#deriv_function is the derivative of deriv_function
deriv_function <- function(x)</pre>
  {
    deriv <- 3^x*log(3) - cos(x) - 5*sin(5*x)
    return(deriv)
 }
#The tolerance is 10^-6
tolerance <- 1e-6
#newton_method applies the newton method using the original function, the #derivative of the original f
newton_method <- function(tolerance,orig_function,deriv_function,start_x)</pre>

  }
    #return the vector of iterations, approximations to the root, the original
                                                                                        #function evaluated
    return(ls = list(iter_vector = iter_vector,x_vector =
                                                                                        x_vector, orig_function
#use sapply on the grid
# system.time(roots <- sapply(grid, newton_method, tolerance = tol, orig_function = orig_function, deriv_
#use parSapply on the grid
library(parallel)
# cores <- max(1,detectCores()-1)</pre>
# cl <- makeCluster(cores)</pre>
# parSapply(cl,grid,newton_method,tolerance = tol, orig_function = orig_function, deriv_function = deri
# stopCluster(cl)
```

There seems to be an infinite number of roots so I just chose the interval [-20,0] to apply the Newton method on. Unfortunately, it was taking my computer way too long to get results using sapply and parSapply. However, I suspect that in this problem, parSapply may be more useful since we are dealing with a large grid and so parallelism would be more appropriate to use.
